INTRODUCTION

The minerals industry is by far the largest single contributor to the valuation of the State of Wyoming. 1987 valuation on minerals produced in 1986 was $3,581,548,229. This is 60% of the state's total valuation and places Wyoming among the top ten mineral producing states in the nation.

This report outlines the distribution and status of the minerals industry in Wyoming during 1986. The primary mineral commodities produced in the state are reviewed individually and a section on historical mineral production is included in the Yearbook. This section enumerates yearly production figures for the state's primary mineral commodities: bentonite, coal, natural gas, petroleum, trona, and uranium from their first commercial development to 1986. The production projections for the next five years give an indication of growth or decline of a particular mineral commodity in both the state and individual counties. Estimates beyond five years are not made because of increasing difficulty in making accurate predictions due to changing economic factors, governmental regulation, decreasing reserves and international developments.

The narrative sections present an overview of the minerals produced in the state and the status of the mineral industry in each county.

The reader desiring more detailed information on the location of various projects or resources is referred to the Oil and Gas Map of Wyoming and the Mines and Minerals Map of Wyoming, and The Construction Materials Map available from the Geological Survey of Wyoming and the EDSB Mineral Development Monitoring System.

Bar graphs for county mineral valuation were prepared for those counties where minerals accounted for a least 25% of the total assessed valuation.

Production figures in this Yearbook are net or taxable figures and do not include federal or state royalty production because it is not included in the assessed valuation.

Appreciation is extended to the mineral companies of Wyoming for their assistance and cooperation in providing estimates of production during the next five years. Also, help and information provided by Ken Uhrich, Jim Felton, and Rocky Hopson of the Ad Valorem Tax Division of the State Department of Revenue and Taxation proved invaluable. Special thanks are extended to Gary Glass and his staff of the Geological Survey of Wyoming for assistance in estimating future production levels. Also, much valuable data was supplied by Don Basko of the Wyoming Oil and Gas Conservation Commission.

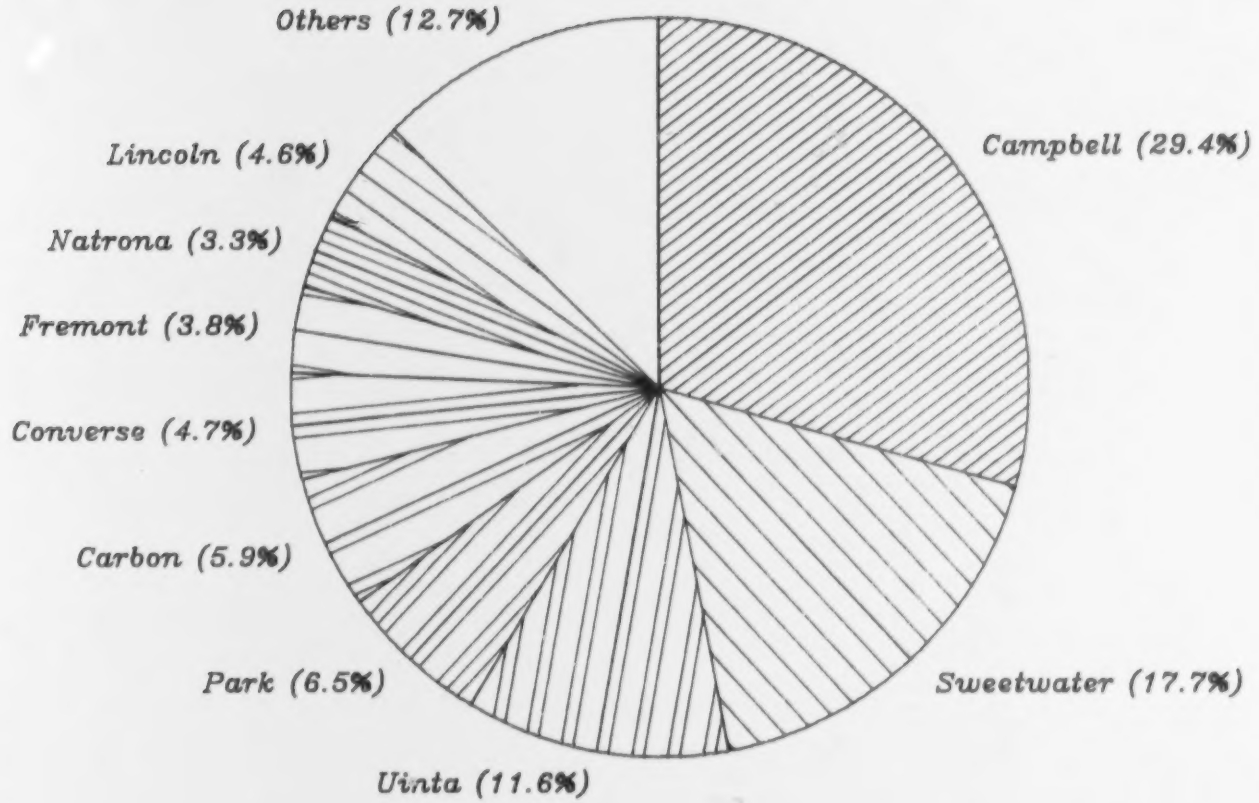
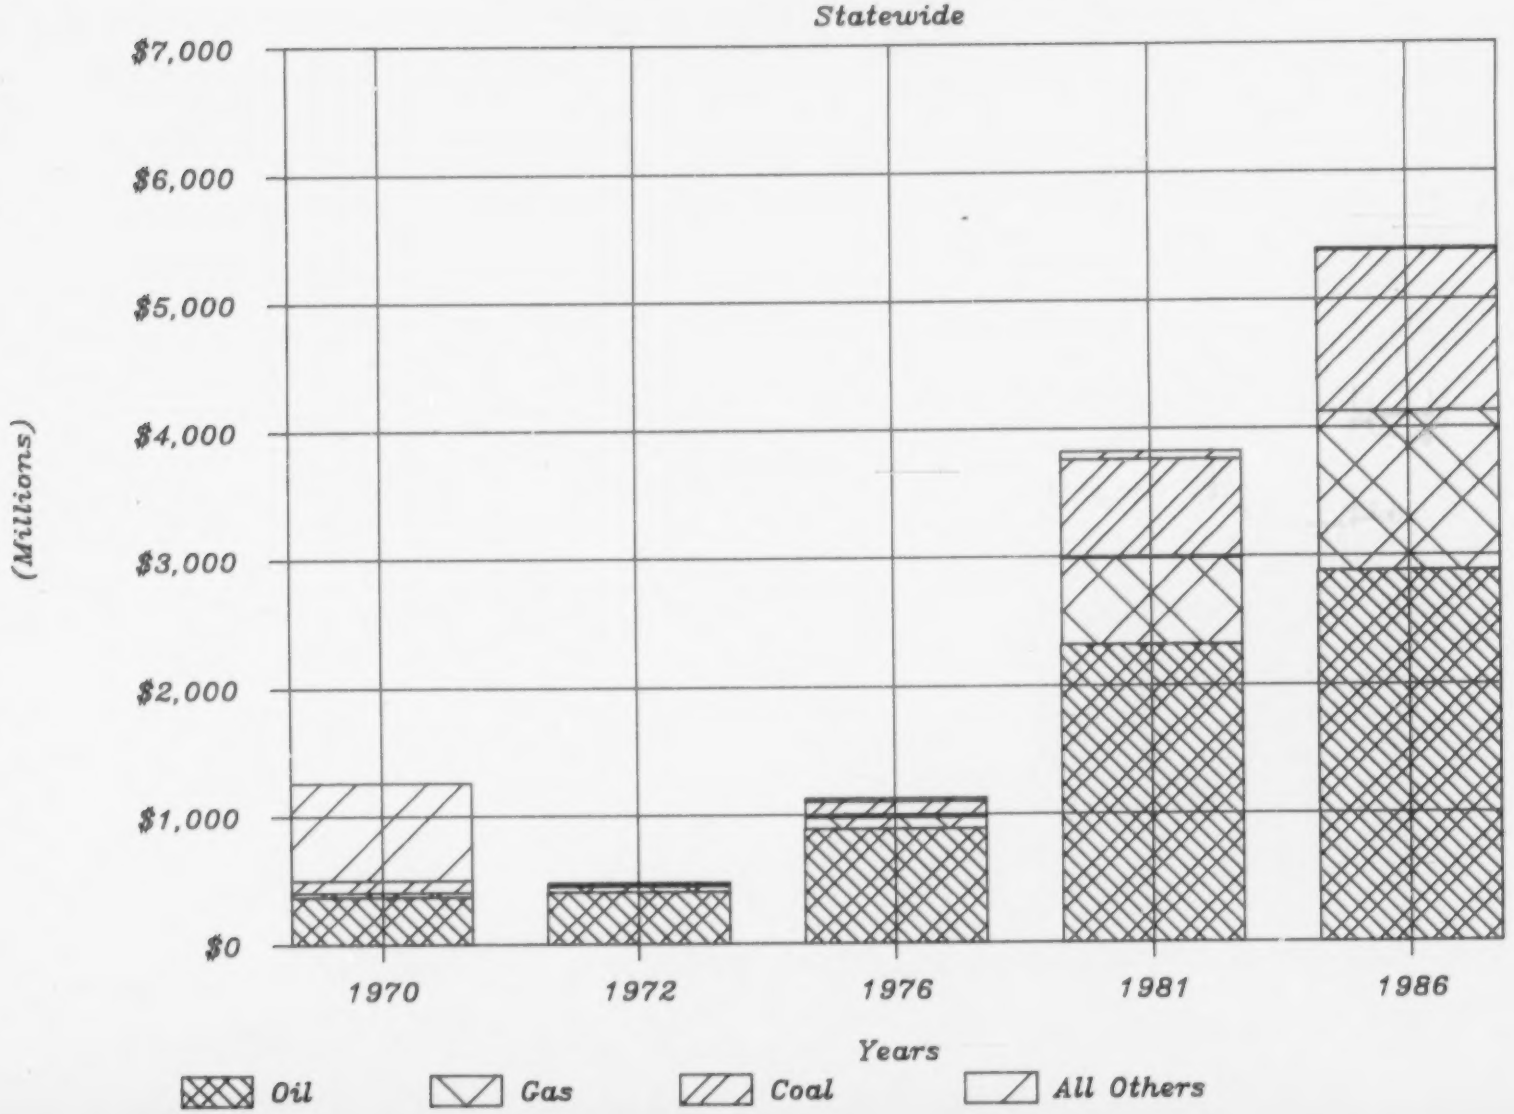
Total 1987 Assessed Mineral Valuation

Total Valuation = $3,581,648,740



Assessed Valuation on Production



WYOMING MINERAL INDUSTRY

TAX TABLES

The ten tables in this section illustrate the tax situation for the Wyoming Minerals Industry since 1969. The significance of 1969 is that it was the year the severance tax on minerals was initiated.

Tables are as follows:

I Assessed Valuation on Production, 1969 - 1987

II Ad Valorem Tax Paid on Production, 1969 - 1987

III Assessed Valuation Per Unit of Production, 1969 - 1987

IV Severance Tax Collections, 1969 - 1987

V Severance Tax Rates, 1969 - 1987

VI Severance Tax Distribution, 1987

VII Sales and Use Tax - Fiscal Year

VIII Government Royalty

IX Summary Table

X Mineral Income to the State, 1971 - 1987

WYOMING MINERAL COMMODITIES REVIEW

1987

BENTONITE

Bentonite is a clay mineral which is the result of the alteration of volcanic ash. Wyoming bentonite originated from volcanic ash ejected in western Wyoming and Idaho during the late Cretaceous period about 120,000,000 years ago. Prevailing westerly winds blew the ash eastward and deposited it in the areas now occupied by bentonite deposits. Wyoming bentonite occurs in the Big Horn Basin, the southern Powder River Basin, and along the western edge of the Black Hills in the northeastern corner of the state.

Bentonite is a clay mineral composed of microscopic platelets consisting of layers of aluminum hydroxide held between layers of silicate atoms. These platelets are stacked one on top of the other. Water can penetrate between layers of platelets, causing the entire structure to swell. Wyoming bentonite has sodium atoms interspersed between these layers of platelets at intervals. Other types of bentonite have calcium between the platelet layers. Sodium bentonite has greatly increased swelling characteristics. Wyoming sodium bentonite, when wet, increases as much as fifteen times its original volume.

Bentonite was used by area Indians as a bleaching clay and washing agent before the white man ventured into what is now Wyoming. Bentonite bogs or "soap holes" caused the loss of some cattle to pioneers, but it was utilized as an emergency substitute for axle grease, as a curative pack for inflamed horses' hoofs and as waterproofing for the roofs of dwellings.

Bentonite was originally named taylorite for William Taylor of Rock Creek, who first made commercial shipments of the clay in 1888. Dr. S. H. "Sam" Knight, State Geologist of Wyoming, renamed the clay bentonite when he learned that taylorite had previously been used in England as the name for

another mineral. The term bentonite comes from the Fort Benton shale member of the Mowry formation, where the mineral occurs.

The first sales of Wyoming bentonite were to eastern plants for use in the manufacture of cosmetics. Production remained at a low level until the 1920's, when bentonite's usefulness as a binding agent in foundry sand and as an additive to oil well drilling mud were first discovered.

The U. S. Bureau of Mines economic mineral publications first separated bentonite from "other clays" in 1931. The Wyoming Ad Valorem Tax Division has maintained separate bentonite production statistics since 1927.

The first bentonite mill in Wyoming was constructed at Cheyenne in 1920. The bentonite used in this plant was mined near Medicine Bow. The first mills near the Black Hills, in the northeastern part of the state, were constructed at Newcastle, Osage, and Upton in 1926. Production began in the northern Black Hills near Belle Fourche in the late 1930's. Later, other high grade deposits were discovered in the Big Horn Basin and the Kaycee area of the Power River Basin.

Wyoming bentonite production has risen from 1,141 tons in 1927 to 1,818,502 tons in 1986. The accompanying table shows historical Wyoming bentonite production.

Estimates of remaining Wyoming bentonite reserves vary widely. A report of the American Institute of Mining Engineers gives a figure of 1,149,000,000 tons of in-place reserves, while the 1980 edition of the U. S. Bureau of Mines Minerals Facts and Problems lists reserves of 200,000,000 tons.

Bentonite deposits either crop out at the surface or are buried shallowly, so mining operations consist of removing any overburden present and loading the bentonite into trucks for transport to a mill. Due to shallow

burial and the loose unconsolidated nature of the surrounding sediments, no underground mining of bentonite has been attempted. When the bentonite arrives at the mill, it is segregated into piles according to physical characteristics. Materials from these piles are blended to obtain a product with the desired characteristics.

In the mill, the bentonite is first broken into small chunks, screened, and conveyed through a dryer. Temperature of the dryer is critical since temperatures that are too high can destroy the desired properties of the bentonite. Natural gas has been the fuel used in the dryers, but coal and some air drying are now utilized in several operations.

Drying removes about 25% of the moisture in the bentonite. After drying, the clay is pulverized to a variety of size ranges. After sizing, bentonite is either packed in 50, 75, or 100 pound bags or bulk shipped in covered railroad cars.

Currently the single largest market for bentonite is the oil and gas industry, which uses bentonite as a drilling mud additive. Fifty percent of Wyoming bentonite is used in drilling muds. Bentonite's colloidal properties allow heavy well cuttings to be suspended, helps lubricate drilling equipment, cakes the sides of the drill hole to prevent caving, and prevents seeping of ground water into the hole and drilling fluids out of it into surrounding rocks.

The foundry industry consumes 20% of the state's bentonite. Bentonite is used as a molding sand binder. The clay's superior binding properties allow the sand to be formed into shapes that will not fracture or disintegrate during molding operations.

Iron ore pelletizing has used 20% of the bentonite produced. However, it appears that an organic binder may takeover this application.

The remaining 10% is used in a myriad of applications, a sampling of which are: animal feed, ceramics, water softening, cement manufacture, laxatives, crayons, paint, insecticide, reservoir liner, and medicines.

The Wyoming bentonite industry is facing a decline in markets due to a reduction in oil well drilling, the slump of the automobile industry, loss of the iron ore pelletizing application, and sluggish construction activity. Long range prospects are favorable, but bentonite production will probably flucuate in the near term.

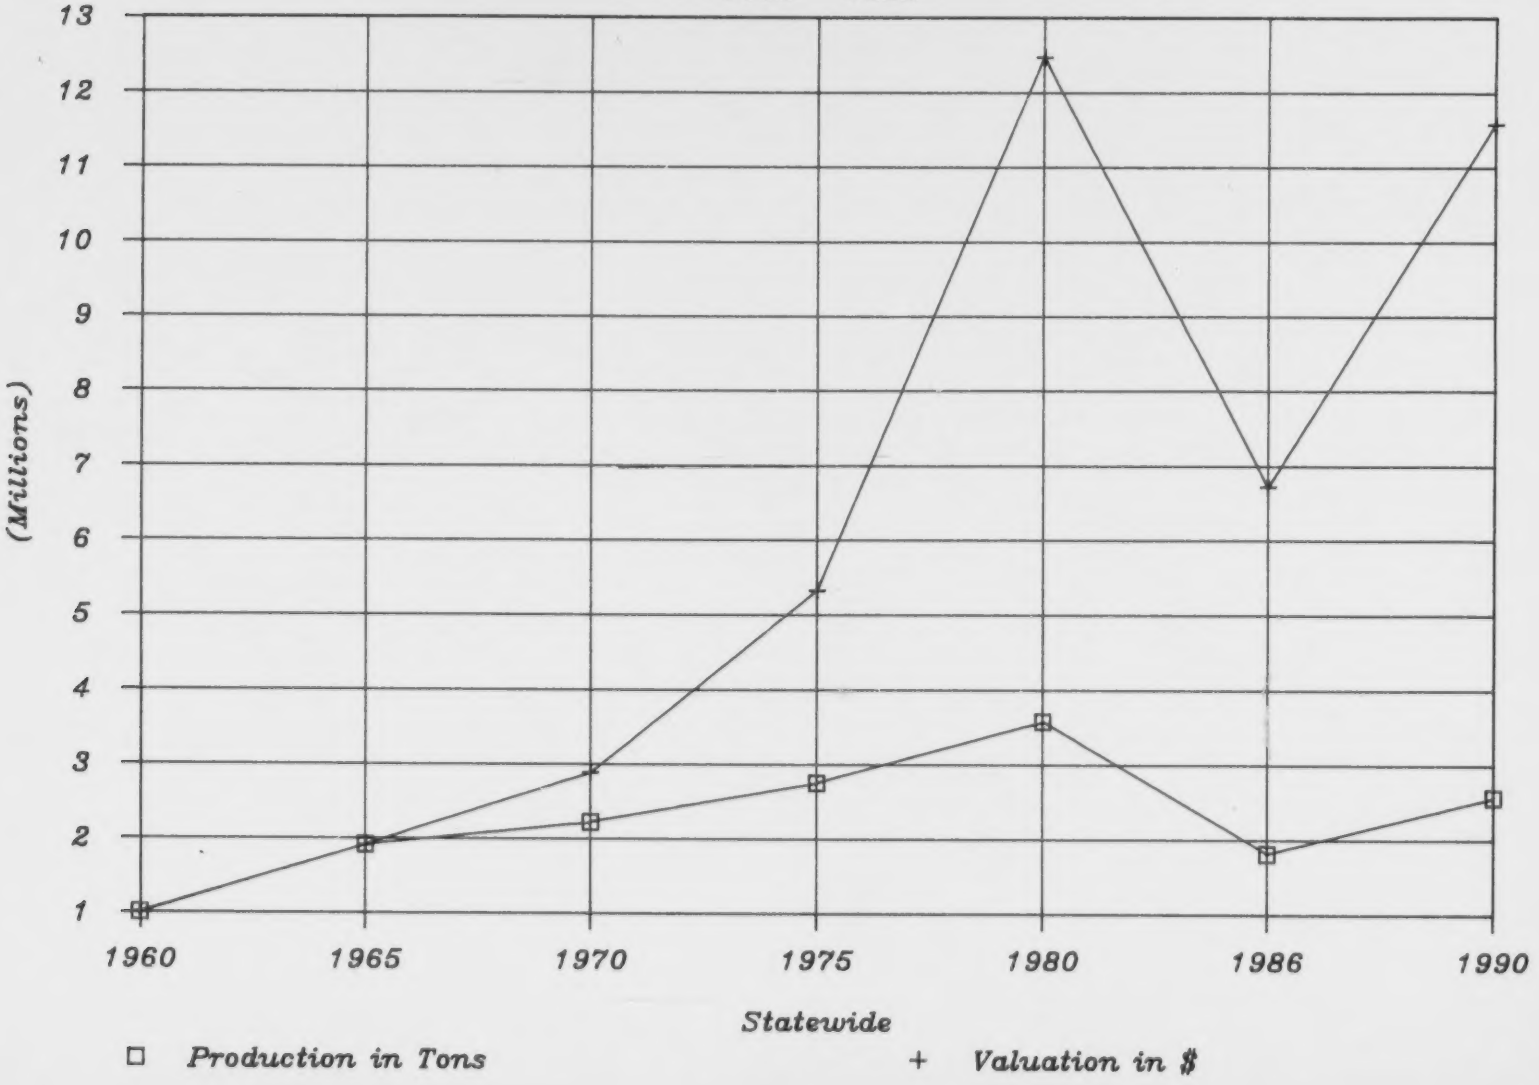
Bentonite Production and Valuation

1960 – 1990



COAL

Coal results from the burial and compression of large amounts of vegetation. Increasing depth of burial results in the addition of heat which alters the original vegetation physically and chemically.

Wyoming's coal deposits accumulated during two geologic periods, the later Cretaceous and Early Tertiary, between 75 and 45 million years ago.

During late Cretaceous time, Wyoming was a low land area, periodically covered by a shallow sea which advanced and retreated from east to west. When the sea retreated, low lying coastal swamps developed where extensive vegetation grew, died and accumulated on the swamp bottoms. When the sea re-advanced, the plant material was buried by silts and clays. This cycle was repeated many times, with the earlier deposited material being buried deeper and deeper and ultimately being converted into coal by heat and pressure. Wyoming's Cretaceous coals are commonly thin, seldom exceeding 10 feet in thickness.

Conditions were different in early Tertiary Time, when the other sequence of Wyoming coals developed. The sea had disappeared, and various ranges of the Rocky Mountains had risen. A number of basins developed between these ranges, and large amounts of vegetation accumulated in these basins. These Tertiary coals are typically much thicker then the earlier deposits, with beds of 30 to 100 feet common, and a maximum known thickness of over 200 feet.

Coals are ranked according to composition and heating value. Peat, which consists of lightly compressed dried vegetation, is not considered a coal, although it is used as a fuel in Ireland and northern England. The ranks of coal are as follows:

Name	Amount of Carbon	BTU Content	Volatiles	Moisture
Anthracite	86 - 98%	16,000 - 20,000	5%	0%
Bituminous	55 - 85%	11,000 - 16,000	25%	20%
Subbituminous	30 - 55%	8,300 - 11,000	40%	30%
Lignite	10 - 30%	4,000 - 8,300	50%	40%

These ranks are divided into smaller categories in detailed classifications. Wyoming's coal is subbituminous in grade. It contains more moisture and less sulphur than many equivalent coals from the east and midwest.

The first written account of coal in Wyoming was made in 1843 by Captain John C. Fremont, "The Pathfinder". He referred to the appearance of coal in what was probably Cumberland Gap, near Kemmerer.

Captain John R. Stansbury, U. S. Army Corp of Engineers, reported seeing large outcrops of coal near Rock Springs and at Point of Rocks, twenty-five miles east of Rock Springs, in 1852.

The first use of Wyoming coal was made by the Army to heat winter quarters and in stage line forges in the mid-1800's.

The Union Pacific Railroad began prospecting for coal along its line in Wyoming in 1867, and the first coal mined by the railroad was 650 tons taken at the now abandoned Town of Carbon in 1868.

In 1908, forty years after the first production, coal mining was the leading industry in Wyoming, with a production of over six million tons, one-third of it from the Rock Springs area.

The Kemmerer Coal Company opened mines near Kemmerer about the turn of the century, and Kemmerer Coal is still operating at the present time, the longest continuous operation in the state.

Production increased up to 1947, when eight million tons were produced in

the state, mostly from mines in the Hanna, Rock Springs, and Sheridan areas.

It was at this point that the railroads began the change from steam to diesel locomotives, and as demand for railroad coal decreased, Wyoming production followed it downward. The bottom was reached in 1959 when the state produced less than two million tons.

Beginning in the mid-1960's, interest in Wyoming coal, as a fuel for thermal electric generation plants, began to increase. This interest was sparked primarily by two factors, physical properties of the coal, and its cost. The physical property of Wyoming coal, which made it attractive to power plant operators, was its low sulphur content, which ranges between 0.5 and 1.5 percent sulphur. This constrasts with eastern coals which range from 5 to 9 percent sulphur. The ability to burn Wyoming coal without installation of expensive exhaust gas scrubbers more than compensated for other detrimental properties, namely low heat value and high water content.

Because virtually all Wyoming coal was strip mined, its cost of production was much less than deep mined eastern coal. In addition, large machinery and the latest technology greatly increased worker productivity, which lowered the price further.

At present, there are twenty-seven active Wyoming coal mines; all surface operations. These mines are concentrated in only a few areas: the Hams Fork Coal Region in Lincoln County; the Rock Springs Coal Region in Sweetwater County; the Hanna Coal Field in Carbon County; the Powder River Coal Region in Converse, Campbell, and Sheridan Counties; and one mine in the Big Horn Coal Field of Hot Springs County.

The Powder River Basin accounts for 81% of Wyoming's production and boasts the three biggest surface coal mines in the nation: Amax's Belle Ayre

and Jacob's Ranch Mines and Atlantic Richfield's Black Thunder Mine. Information on individual mines is available from the State Geological Survey in Laramie or the Minerals Division of EDSB.

Wyoming coal production has increased over 15 fold since 1971 under the impetus of power plant demand. The history of Wyoming coal production is given on the accompanying table.

The future of the Wyoming coal industry is uncertain. Several factors mitigate against Wyoming coal:

1. With the requirement of SO_2 scrubbers on all power plant smoke stacks, regardless of the sulphur content of the coal being burned, eastern and mid-western utilities are leaning toward local, higher sulphur, higher BTU coal to fuel their boilers.

2. Freight rates have reached the point where it costs up to three times as much to transport the coal as the cost of the coal itself. Under these circumstances, local coal becomes much more attractive.

3. The virtual disappearance of the Wyoming coal conversion industry has very much reduced projected in-state coal consumption.

4. Reduced electric power demand has resulted in the cancellation of generating units or entire power plants, significantly reducing potential customers.

Given these negative developments, Wyoming's coal industry is turning its attention toward new markets. One proposed new mine will emphasize the domestic market, an area of small relative demand but one which the existing large mines are not equipped to serve. The most attractive new outlet for Wyoming coal is the export market, primarily the so-called Pacific Rim nations of Japan, China, Taiwan, and the Philippines, along with Mexico.

Acid rain legislation requiring use of low sulphur coal in power plants would result in a large jump in demand for Wyoming coal.

NATURAL GAS

Pure natural gas is composed of the simplest hydrocarbon, methane, CH_4. Natural gas, as it comes from the well, contains a number of different substances, including: ethane, propane, butane, and pentane (hydrocarbons), also carbon dioxide, helium, hydrogen, sulfide, and nitrogen.

Natural gas processing plants remove impurties in the gas and/or compress it to increase density in order to reach the heating standards of commercial gas. The materials removed from the gas by these plants are often valuable in themselves. Propane and butane are used as fuels, while ethane, pentane, and sulphur are utilized by the chemical industry. Hydrogen and helium are important industrial gases, while nitrogen, though often simply vented to the atmosphere, is being reinjected in secondary oil recovery in the Overthrust Belt. Carbon dioxide is also utilized in secondary oil recovery, as well as serving as an important refrigerant when in the liquid or solid form.

Natural gas occurs in three ways:

1. Free natural gas unassociated with crude oil.
2. Associated gas overlying and accompanying crude oil in the same reservoir.
3. Dissolved gas, which is gas in solution with the oil under reservoir conditions.

Pipeline quality natural gas has a heating value of about 1,000 calories per cubic foot. It burns with a bright flame, and the products of its combustion are carbon dioxide and water vapor. The high BTU output, plus the benign combustion products, make natural gas an excellent domestic fuel.

Wyoming has produced some natural gas since 1903, with early production coming from the Wind River and Big Horn Basins. Before 1918, Wyoming's

natural gas production was included with Utah and Colorado, not allowing an individual state breakdown.

The Overthrust Belt leads Wyoming's geologic provinces in natural gas production followed by the Green River Basin, The Wind River Basin, and The Powder River Basin. As the Riley Ridge project comes on line overthrust production will continue to increase.

Wyoming currently ranks seventh in natural gas reserves in the United States. The three leading states, Texas, Louisiana, and Alaska, alone, account for about three-fourths of the total reserves.

Wyoming is sixth in natural gas production behind Texas, Louisiana, Oklahoma, New Mexico, and Kansas, in that order.

Industrial, commercial, and domestic heating and a fuel for industrial processes have always been, virtually, the only markets for Wyoming natural gas.

The precipitous drop in oil prices have contributed to some decline in natural gas production, since much gas is produced as a consequence of oil drilling.

Since this country is self-sufficient in natural gas, the oil price drop has not had a similar effect on fallen gas prices, although they have come down from earlier levels.

The accompanying table shows historical Wyoming natural gas production.

PETROLEUM

The first recorded reference to the occurrence of oil in Wyoming dates back to 1833, when Captain Bonneville visited the "Great Tar Spring" on the Popo Agie River near present day Lander.

The first commercial marketing of oil occurred in 1851 from an oil seep on Poison Spider Creek, west of present day Casper. Records indicate that Jim Bridger, Kit Carson, and others mixed the oil with flour and sold the product to settlers as axle grease.

The first oil field was discovered by Mike Murphy in 1884, when he drilled a 300 foot well near the "Great Tar Spring". This field, Dallas Dome, is still producing oil, 100 years after its discovery.

Pennsylvania Oil and Gas Company built the first small refinery in Wyoming at Casper in 1895. During the period 1900-1920, drilling revealed several of the state's largest fields, including Oregon Basin and Elk Basin in Park County, Garland in Big Horn County, and Lost Soldier in Sweetwater County.

The lack of nearby markets and the high cost of transporting oil by rail, resulted in low demand for Wyoming oil, and crude prices dropped to as low as 10¢ per barrel in the 1930's. It was not until World War II that development moved into full swing. This expansion continued into the 1970's.

Oil is derived from the alteration of organic matter by heat and pressure. Petroleum originates in sedimentary rock environments, but may migrate to other locations, so that there are oil reservoirs known from volcanic and metamorphic rock sequences as well. Most oil is found in sedimentary rocks, in occurrences which may be divided into structural or stratigraphic traps. A structural trap is one where the oil is maintained in place by mechanical means, such as,

folding, faulting, or some combination of the two. Stratigraphic traps involve a change in rock type, from permeable to impermeable, with the oil held in the permeable portion. A stratigraphic unit which changes from a sandstone (permeable) to a shale (impermeable) is an example of a stratigraphic trap. Most of the early discoveries in Wyoming were in large structural traps with obvious surface expression. Modern exploration is focused on deep, subtle structures using sophisticated seismic techniques to discover new reserves. The delineation of stratigraphic traps is based on careful analysis of trends and rock types along with the application of interpretation and imagination by petroleum geologists.

Reservoir rocks in Wyoming range from Tertiary to Precambrian in age. In general, fields in stable interior basin areas are characterized by stratigraphic traps and produce from younger (Cretaceous and Tertiary) formations. Fields in more highly deformed basin margins are usually characterized by structural traps, and production is from older rocks.

The largest oil producing regions in Wyoming, in order, are: the Powder River Basin, Green River Basin, Big Horn Basin, Overthrust Belt, and Wind River Basin.

Early oil production in Wyoming peaked in 1923, after discovery and development of large fields, such as: Salt Creek, Elk Basin, Oregon Basin, and Hamilton Dome. A long period of decline followed these early discoveries until the second World War led to a resurgence which continued to 1970, when the maximum annual production of 155,743,349 barrels was recorded. Since 1970 production has been steadily declining, due to depletion of the old large fields, like Salt Creek. At present, over 50 percent of Wyoming's production comes from ten large fields which average over 50 years in age. Newer disco-

veries in the state are concentrated primarily in Campbell County (Hilight, Raven Creek, Hartzog Draw fields) and the Overthrust Belt.

Wyoming ranks sixth in crude oil production, behind Texas, Alaska, Louisiana, California, and Oklahoma. However, it dominates Rocky Mountain production, with 44% of the production from the area, and 64% of the reserves.

The dominant use of petroleum is as a fuel for internal combustion engines or industrial and residential heating. However, petroleum derivatives are used to manufacture many kinds of lubricating and hydraulic fluids, fibers, medicines, plastics, and a number of other products, ranging from paints to synthetic rubber.

Although production has been slowly declining, valuation of oil production in Wyoming increased dramatically since the initiation of OPEC price increases in the early 1970's, and since decontrol of domestic oil prices in 1980. In 1981, oil production accounted for 44% of the total state valuation, some 3.6 billion dollars. Oil valuation has declined since 1981 and this decline has been precipitous in the last 21 months, but petroleum will remain the state's most valuable mineral product.

Currently, six refineries are operating in Wyoming with a total capacity of 175,000 barrels per day. These refineries can process less than half of Wyoming's daily crude oil production, the remainder being transported by pipeline to neighboring states.

The most recent estimate of discovered oil reserves in Wyoming, made by the American Petroleum Institute, reports a total state reserve of 800 million barrels. This figure has been declining steadily since 1971, and although new discoveries in the Overthrust Belt will slow the decline, the downward trend

will continue.

The jump in production seen in 1984 is due to liquids stripped in the Overthrust gas processing plants being included in oil production.

Given new exploration techniques, along with enhanced recovery methods which are coming into increasing use, Wyoming will continue to lead the Rocky Mountain region in oil production for some time. If oil shale utilization ever reaches large scale fruition, Wyoming will be a significant oil producer well into the next century.

The collapse of oil prices which has devastated the U.S. petroleum industry has not spared Wyoming. Production totals in 1986 were greatly lowered, and the trend will be downward for several more years.

Rebound will occur, but the question is, what remnant of the oil industry will survive, and in what condition will U.S. energy security be when conditions finally improve.

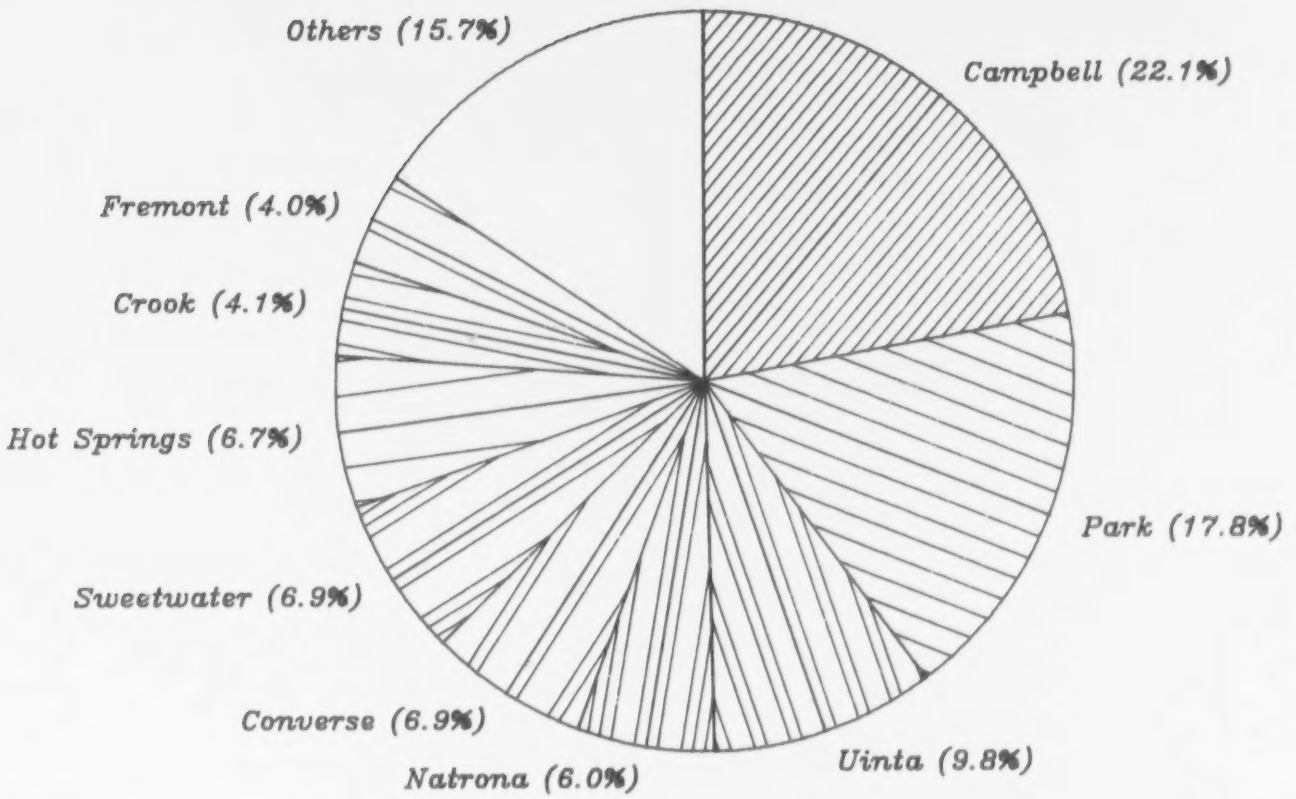
1986 Crude Oil Production by County

Total Production = 111,148,577 Barrels



TRONA

The world's largest deposit of trona is found in Wyoming's Green River Basin. From the deposit, the state produces about 95 percent of the nation's supply of natural soda ash. Several deposits of natural soda ash are known in the western United States, but only Wyoming and California have active mines. Deposits have also been identified in several other countries, but the only one currently producing is Kenya.

Trona is a water-bearing sodium bicarbonate compound with many uses. Trona originated as a precipitate from a large fresh-water lake, Lake Gosiute, which covered as much as 15,000 square miles of surface in southwestern Wyoming. The trona was precipitated when Lake Gosiute underwent a period of restricted circulation and became highly saline at the same time as elevated temperatures resulted in increased evaporation.

More than 40 individual beds of trona underlie an area of about 1,300 square miles. It is estimated that some 50 billion tons of mineable trona, plus an additional 30 to 40 billion tons of marginal trona, are contained in these beds.

In 1938, Mountain Fuel Supply Company drilled an oil and gas test well northwest of Green River, Wyoming, and discovered a brine rich in trona. Exploration by the Union Pacific Railroad, in 1940-1942, indicated the presence of extensive reserves of trona. In 1946, Westvaco, the predecessor of FMC Corporation, sank a 1500 foot shaft to the main trona deposit and constructed a pilot refinery at the surface. The first soda ash was produced by FMC in 1950, with Stauffer Chemical coming on line in 1962, Allied Chemical in 1968, Texasgulf in 1975, and Tenneco Oil Company in 1982.

All Wyoming trona mining is done underground. Room and pillar methods and coal mining equipment, modified to withstand the harder ore, are used.

Both conventional and continuous mining techniques have been traditionally used, but recently long wall mining has been successfully employed.

In the past, soda ash was primarily produced synthetically by the Solvay process. This process combines salt (sodium chloride) and calcium carbonate (limestone) to make sodium carbonate (soda ash). The last plant using the Solvay method in this country was shut down last year. The Solvay plant shutdowns were the result of high capital, labor, and energy requirements, but the greatest factor was the environmental considerations. For each ton of soda ash produced by the Solvay process, about 1.7 tons of waste are generated, which poses an enormous disposal problem.

Trona is refined by first subjecting the ore to a heat of 400°F to remove water of crystallization, combustible materials, and carbon dioxide. This crude soda residue is then taken into water solution and filtered to remove insoluable residues. The filtered material is then dried. The final product is pure soda ash.

Trona's primary use is in glassmaking, which takes around 55% of the United States' consumption. The chemical industry accounts for 23% of consumption, followed by soap and detergent at 5%, pulp and paper manufacturing at 4%, water treatment at 3%, and 10% in various applications including pharmaceuticals, photography, metallurgy, and petroleum refining.

Wyoming trona production has grown from 29,658 tons in 1950, to 11,919,530 tons in 1986. Valuation of 1986 production was $105,566,325. The short-term future of Wyoming trona is less favorable than earlier predictions, due to slumps in housing and the automobile industry, two prime users of glass, which

is trona's most important market. In the longer term, significant growth in Wyoming's trona market would seem to be likely to come from Europe, where most soda ash is currently produced by the Solvay process, with the same problems there as in this country.

China has expressed interest as well, but she has abundant raw materials for Solvay extraction, and is currently building a large plant to utilize them using this process.

Whatever the demand, Wyoming possesses the resources to meet it. If trona had been mined at the current rates since the year 1 A.D., only 20% of the known reserves would have been depleted, and if mining had proceeded at the same rate since the rise of the first dynasty in Egypt, 50% of the known reserves would still remain untouched.

An annual compilation of trona production in Wyoming is given in the following table.

HISTORICAL TRONA PRODUCTION

Year	Net Tons
1950	29,658
1951	76,769
1952	56,733
1953	262,001

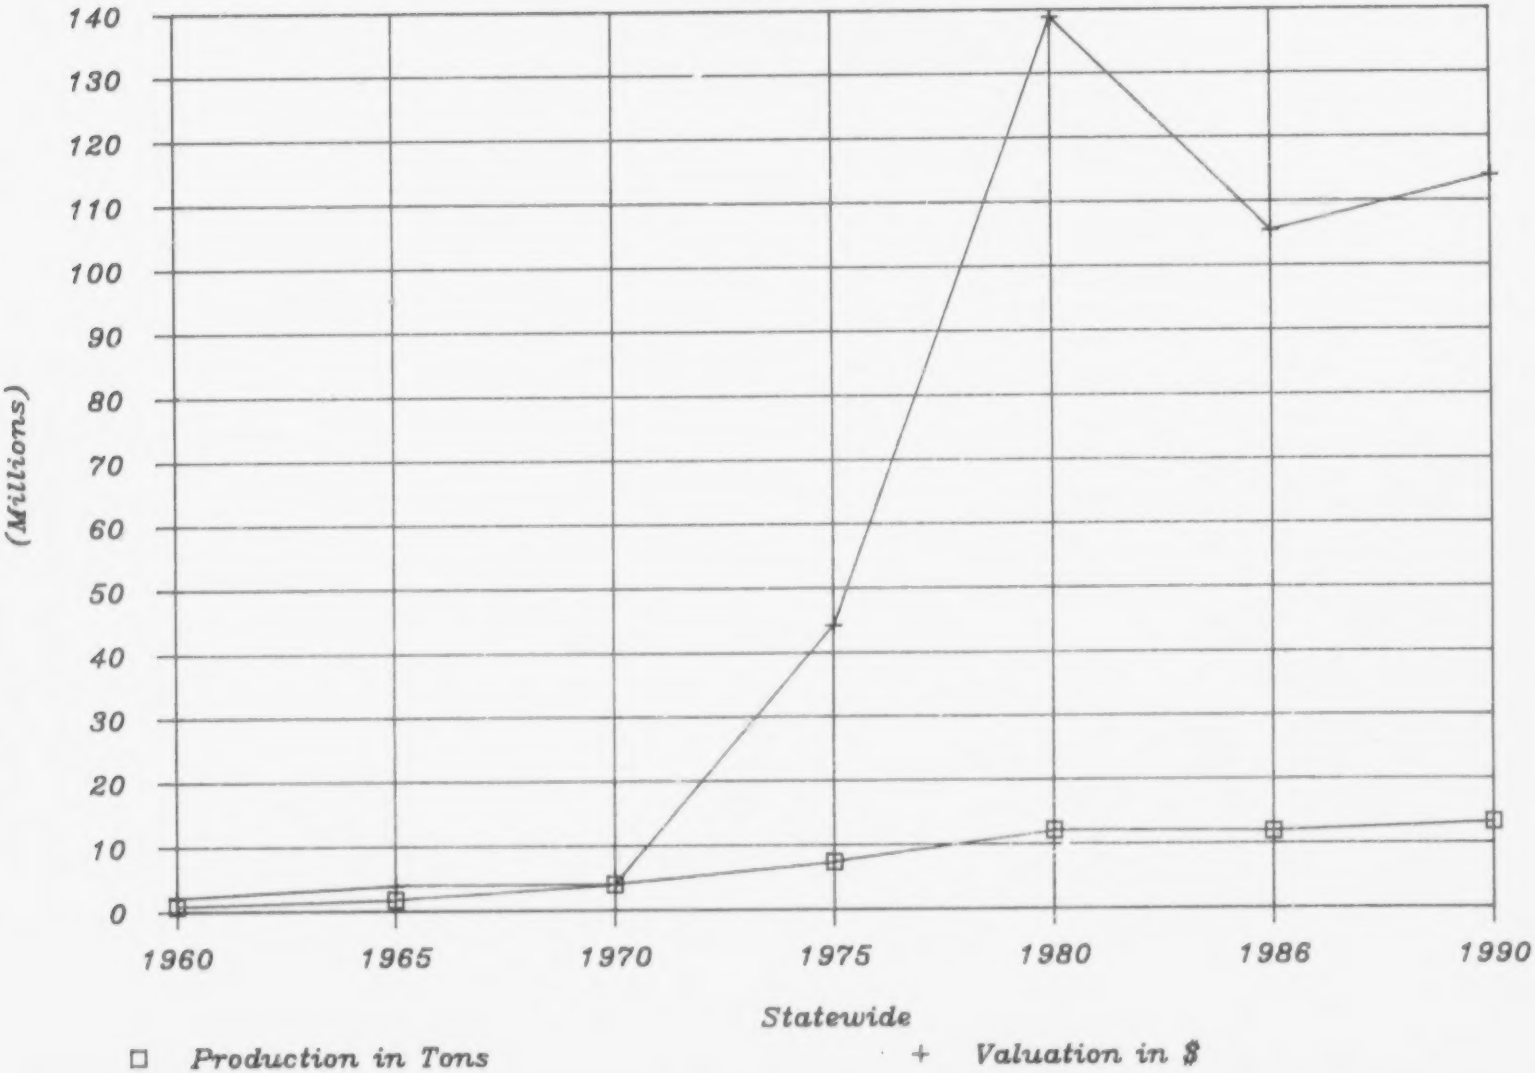
1960 – 1990



URANIUM

Uranium was discovered as an element in 1789 and isolated as a metal in 1842. A few minor uses for uranium salts and medical demand for radium created a small market in the 1920's and 1930's. So little was known about possible ore sources in the United States that the uranium ore used in the production of the two atomic bombs dropped on Japan came from the Belgian Congo. The Atomic Energy Commission was appointed by President Truman in 1946. In the late 1940's and early 1950's the public was encouraged to prospect for uranium and the first great uranium rush was on.

Uranium is a widespread, though uncommon, primary constituent of crystalline rocks of the earth's crust. As a result of weathering processes, it is often removed from these source rocks and redeposited in sediments. Uranium deposits are known from rocks as old as Precambrian, and as recent as Pleistocene, and all ages in-between.

The most important deposits of uranium in Wyoming occur in permeable sandstones of Tertiary age. The uranium was originally contained in the crystalline rocks which form the cores of the state's mountain ranges. The uranium was leached from these rocks and precipitated in the much younger sandstones.

Uranium ore is recovered by open pit, underground, and solution mining methods. Open pit and underground mining is carried out in the usual manner, the only difference being that the material to be removed is determined by using a scintillation counter to delineate the radioactive ore.

In solution mining, a shaft is drilled into the ore body. Chemicals are introduced down this shaft which dissolve the uranium out of the rock. The

uranium-containing solution is removed through another well or wells drilled to the depth of the ore body. The solution on the surface is processed much as the solutions obtained by conventional milling methods to remove the dissolved uranium. Due to the toxic nature of the solutions used, great care must be exercised in solution mining operations to prevent ground water contamination.

Milling involves grinding and crushing the ore, after which it is treated with acid to take the uranium into solution. The leachate is treated with various chemicals to concentrate the uranium and simplify it chemically. The final concentrate is evaporated to yield "yellow cake". The yellow cake consists almost entirely of uranium 238 and a small percentage of uranium 235, the fissionable isotope. The uranium must be enriched to around 3.5% U 235 for power reactor use, while weapons grade material has a U 235 content of over 90%. The yellow cake is shipped to various conversion and enrichment facilities to be upgraded to the required level.

The primary uses of uranium are as fuel for nuclear reactors and national defense. The drop in power demand coupled with uneasiness over plant reliability have combined to slow the construction of nuclear power plants, and greatly reduce the requirements for uranium. Defense requirements are difficult to determine, but new weapon construction plus upgrading of existing stock piles (nuclear warheads deteriorate through time) has increased, though not enough to increase demand significantly. Other uses for uranium are in X-ray tubes, ultraviolet lamps, glass colorants, ceramics, and steel.

Wyoming's first production of uranium occurred in 1953, when 5,156 tons of ore were mined. The largest production of 5,517,070 tons was attained in 1978. Wyoming ranks second to New Mexico in both uranium production and amount of reserves. The history of Wyoming uranium production is given in the accom-

panying table.

As of January 1987, Wyoming had one active uranium surface mining operation and three in-situ projects. Given the availability of cheap high grade ore from abroad coupled with the difficulties of the domestic nuclear power industry, it seems unlikely that the uranium mining and milling industry will ever again play a significant role in Wyoming's mineral economy. The reserves are here, but market and competition factors make the future appear bleak, to say the least.

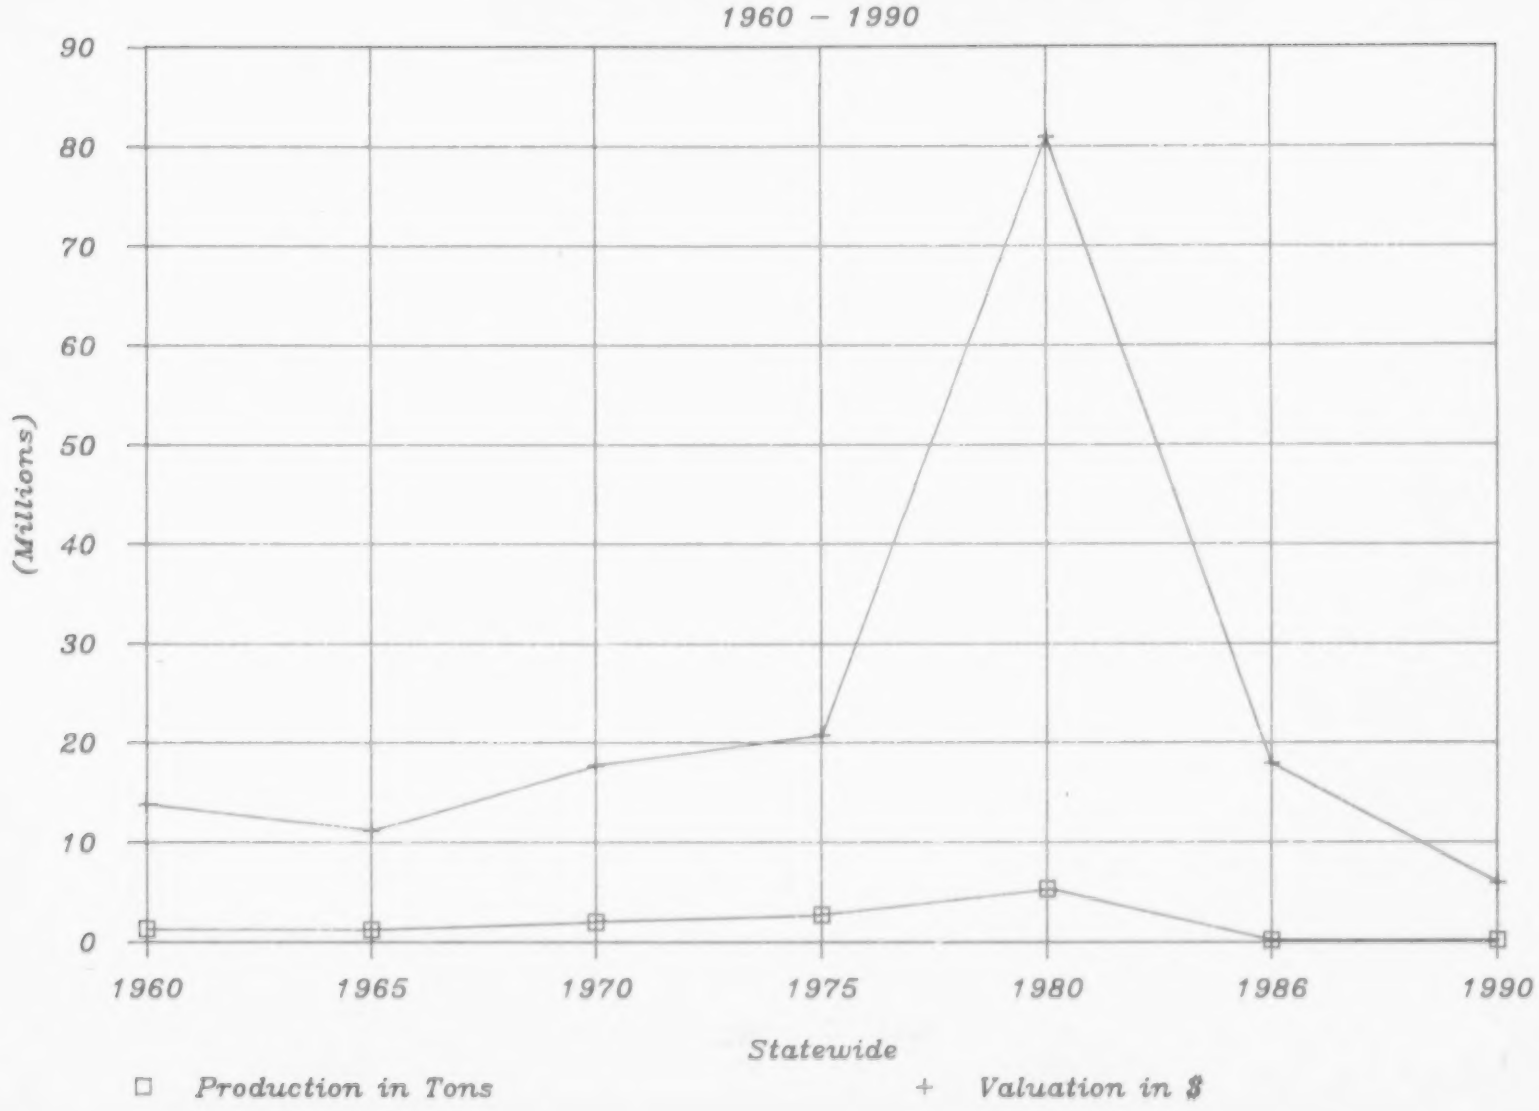
Uranium Production and Valuation



MISCELLANEOUS MINERALS

COPPER

Copper was the first metal utilized by man over 6,000 years ago. Native uncombined copper was utilized for tools, weapons, and jewelry due to the ease with which it could be shaped.

Currently, over half of the copper produced is used in the electrical industry for wire, equipment, and components. Next to silver, copper has the highest electrical conductivity of any metal. Other uses of copper are in plumbing, instruments, household utensils, decorative items, and coinage.

Copper occurs as the native metal or combined in sulphides, oxides, and carbonates. These secondary compounds are the result of weathering and concentration of copper from its original source in low silica igneous rocks.

Copper mineralization occurs sporadically throughout every mountain range in Wyoming. Copper mineralization is most common in Precambrian rocks, but is found in younger rocks in places such as the northern Laramie mountains and the Hartville uplift.

In the interval between 1899 and 1908, over 23.5 million pounds of copper were produced in Wyoming, mostly from the Encampment district, west of Laramie, and in this period Wyoming was one of the leading copper producing states in the nation. Copper production increased during World War I, mostly from the Hartville area, north of Wheatland. Since that time, Wyoming copper production has been insignificant. Recent speculation concerning reopening of the famous Ferris-Haggerty Mine in Carbon County, along with AMAX Minerals' interest in opening a copper mine in the Kirwin district in the Absaroka Mountains in Park

County, are very unlikely to come to pass as long as world copper prices remain at their current low levels.

DIAMONDS

Diamond is composed of carbon, arranged in a crystal structure which makes it the hardest natural substance known. Diamonds were first prized as gemstones centuries ago in India and Borneo. It was not until much later that the applications of diamond as an abrasive in grinding wheels and drill bits, and as wire drawing dies, were realized.

Diamonds are produced in South Africa, the U.S.S.R., Brazil, and the East Indies. No natural diamonds are produced in the United States, although the General Electric Company has produced synthetic diamonds of industrial grade since 1955.

The primary source of diamonds is the mineral Kimberlite, a greenish gray crystalline rock which is the solidified lava conduit of an ancient volcano. Diamonds are produced naturally in the high pressures and temperatures found in pockets of molten rock deep beneath the surface. Exposure of these Kimberlite pipes results in weathering of diamonds from the rock and their concentration in stream gravels. About 50% of the diamonds recovered are taken by placer mining of old stream channels.

Kimberlite pipes occur along the eastern Wyoming-Colorado border. A number of small (less than 2 mm) diamonds have been extracted from these rocks. Cominco American conducted preliminary evaluation work on the deposits in Wyoming but these efforts have been abandoned.

GOLD

Gold has been treasured since ancient times due to its beauty, permanence, and the ease with which it can be worked. In the latter half of the 20th century, it has become a valuable industrial material, with applications in computers, shielding, high performance welding and other uses. Gold's most widespread use remains as a monetary standard. Nearly half of the gold that has ever been mined is in government vaults.

Gold is one of the "noble" metals. It does not combine chemically with other elements. Gold is found in a wide variety of geologic environments associated with various rocks and minerals. Due to its weight and lack of impurities, it is concentrated by stream action into placer deposits where it is recovered by dredging and washing sediments.

Gold has been found in all of the mountain ranges of Wyoming. Past significant mining operations were located in the Wind River Mountains, the Medicine Bow Mountains, and the Sierra Madre Mountains. No mines in these districts were exploited below 400 feet, and many were abandoned while still in the ore body.

Approximately 325,000 ounces of gold have been produced from Wyoming. No operations are currently active, although current gold prices have stimulated renewed interest and exploration.

GYPSUM

Gypsum has been used since ancient times for carving and decoration. The Greeks used it to manufacture plaster, which remains the principle use for the mineral. In the late 1800's a method to retard the setting of gypsum plaster was developed, and this revolutionized the industry by permitting the use of plaster in construction. The development of prefabricated wallboard revolutionized the industry again in the 1960's. Approximately two-thirds of the gypsum currently marketed is in the form of prefabricated products.

Gypsum is precipitated primarily from sea water, but may be deposited in saline lakes or hot springs. It often occurs as a product of volcanic activity and may occur in metallic mineral veins.

Gypsum, in Wyoming, primarily occurs in layers in Permian, Triassic, and Jurassic red beds at various localities within the state. Some gypsum has been mined in Wyoming since the 1890's, but current production comes from mines in Albany, Big Horn, and Park Counties. Virtually all of Wyoming's gypsum output is utilized in the manufacture of wallboard for the construction industry and the manufacturing of cement.

JADE

Jade has been a prized gemstone in China and the Far East for a long time. It is valued for its toughness, ability to take a high polish, and the ease with which it is carved.

The term jade is applied to two different minerals which have roughly similar properties. The mineral jadeite is a sodium-aluminum silicate. It is hard and tough, and varies from white to greenish-white to emerald green. It has been found in Burma, Southern China, Tibet, Mexico, and South America. No jadeite has been found in Wyoming. The second variety of jade is the mineral nephrite, a calcium-magnesium-aluminum silicate. It is not quite so hard or tough as jadeite. Its color varies from olive-green through dark green to black. Light "apple-green" jade is the most valued. It has been found in China, Turkestan, Siberia, New Zealand, and Alaska, as well as Wyoming.

Jadeite occurs in metamorphic rocks in veins and masses. Nephrite occurs as veins in metamorphic rocks. Wyoming jade occurs as veins in Precambrian metamorphic rocks in the southern Wind River Mountains. Boulders and pebbles of jade occur around the southern end of the Wind River Mountains and on the north end of the Laramie Mountains to the east. Although the jade industry of Wyoming is small, it is well known throughout the world and provides some income and/or a hobby for many people.

ZEOLITES

Zeolites are sodium and/or calcium-aluminum silicate minerals that occur in bedded clay deposits or in vesicles in volcanic rocks. Their current use is in water softening due to their ability to exchange ions with solutions they contact. It is projected that they will be used on a large scale for extraction of radioactive products from nuclear reactor wastes.

The Beaver Rim area of Fremont County contains layered zeolites bedded with clays exposed over a considerable area; however, there is no commercial production at this time.

Tenneco Minerals abandoned their proposed Zeolite operation in Sweetwater County.

CONSTRUCTION MATERIALS

The major construction materials mined in Wyoming are crushed rock for cement, sand and gravel, and limestone. The cement industry is the largest non-fuel minerals industry in the nation. Cement is vital to the construction and road-building industries and is literally the backbone of modern civilization. Wyoming does have one cement plant in Albany County.

Sand and gravel is the only mineral commodity which is produced in all 50 states, and coincidentally is the only one produced in all of Wyoming's 23 counties. Its primary uses are as aggregate for concrete and bituminous mixes, for road bases and coverings and as fill. Pure sand is used in glass manufacture, foundry molding, and metallurgical applications.

Limestone is utilized as a building and decorative stone, road metal, aggregate, and in sugar beet factories where pure limestone is used as a source of lime and carbon dioxide in the refining process.

The Geological Survey of Wyoming has a construction materials map of the state.

COUNTY MINERAL PRODUCTION AND VALUATION

1987

ALBANY COUNTY

Almost 80% of Albany County's mineral valuation in 1987 was on crude oil, with gypsum, cement rock, and construction materials making up the remainder.

Oil production was down in 1986, and valuation per barrel dropped over $10.00. The various factors combined to make total 1987 mineral valuation in the county 1.5 million dollars less than 1986.

BIG HORN COUNTY

Big Horn County's prime mineral product is crude oil. In 1986, oil valuation accounted for 89% of the county's mineral worth. Production decreased by over 750,000 barrels, and a $12.78 per barrel decline in unit value resulted in a valuation decrease of 34 million dollars, a trend that will continue. Natural gas production increased slightly in 1986, and bentonite decreased by nearly 500,000 tons. Gypsum production grew by 65,000 tons. Minor amounts of clay, sand, and gravel were again produced.

CAMPBELL COUNTY

Campbell County leads Wyoming in oil and coal production, and is 8th in natural gas production. Despite a drop of $10.74 in oil valuation per barrel and a 27 cent per ton dip in coal valuation, Campbell County leads all counties in the state with a total mineral valuation of over 1 billion dollars.

The county produced over 24 million barrels of oil in 1986, along with about 104 million tons of coal, 81% of Wyoming's production. Natural gas production rose by nearly 800,000 MCF over 1985.

CARBON COUNTY

Natural gas was the most valuable county mineral commodity in 1986, with a total worth of almost 120 million dollars.

Carbon county produced 2.0 million tons of coal in 1986, down from 3.1 million tons in 1985. The high mining costs in Carbon County will continue to fuel this overall downward trend, and production may well cease altogether toward the end of this decade.

The only uranium ore mined in the state, 226,821 tons, was produced in Carbon County in 1986.

Oil production was down slightly from 2.5 to 2.4 million barrels.

CONVERSE COUNTY

Oil production fell in Converse County in 1986, from 8.9 to 7.7 million barrels. Coupled with a valuation decrease of $11.32 per barrel, total valuation fell 118 million dollars.

Natural gas production fell by almost 3.0 million MCF over 1985, and valuation dropped by .15 per MCF.

Coal production at the county's only mining operation increased nearly 1.3 million tons in 1986.

Some in-situ Uranium mining continues in the County, and more is planned.

GOSHEN COUNTY

Goshen County mineral production consists of a small amount of oil and construction materials.

Its 1987 mineral valuation of 324,000 dollars was one of only two Wyoming counties with mineral production of less than 2 million dollars.

The county's oil is from low production stripper wells and has one of the higher unit valuations in the State, $14.12 per barrel for 1987, a drop of $11.58 from 1986.

The shutting in of oil wells due to declining prices has struck stripper wells first, so Goshen County's oil production, small to begin with, will shrink further.

HOT SPRINGS COUNTY

Oil accounts for 99% of Hot Springs county's mineral valuation. In 1986 production rose slightly by 200,000 barrels, but an $11.80 per barrel drop in price resulted in a drop in valuation of over 82 million dollars.

Coal production at the Grass Creek Mine was 27,545 tons. The company has filed applications to increase capacity to 700,000 tons over the next several years.

Natural gas production and unit valuation in the county held steady.

LARAMIE COUNTY

In 1986 oil production accounted for 79% of Laramie County's mineral valuation, with construction materials accounting for all the rest except for a small amount of natural gas.

Oil production in the county fell by 117,000 barrels, coupled with a valuation decrease of $11.70 per barrel.

The county total of 1,733,032 dollars for construction material valuation reflects continued MX related development in the county.

LINCOLN COUNTY

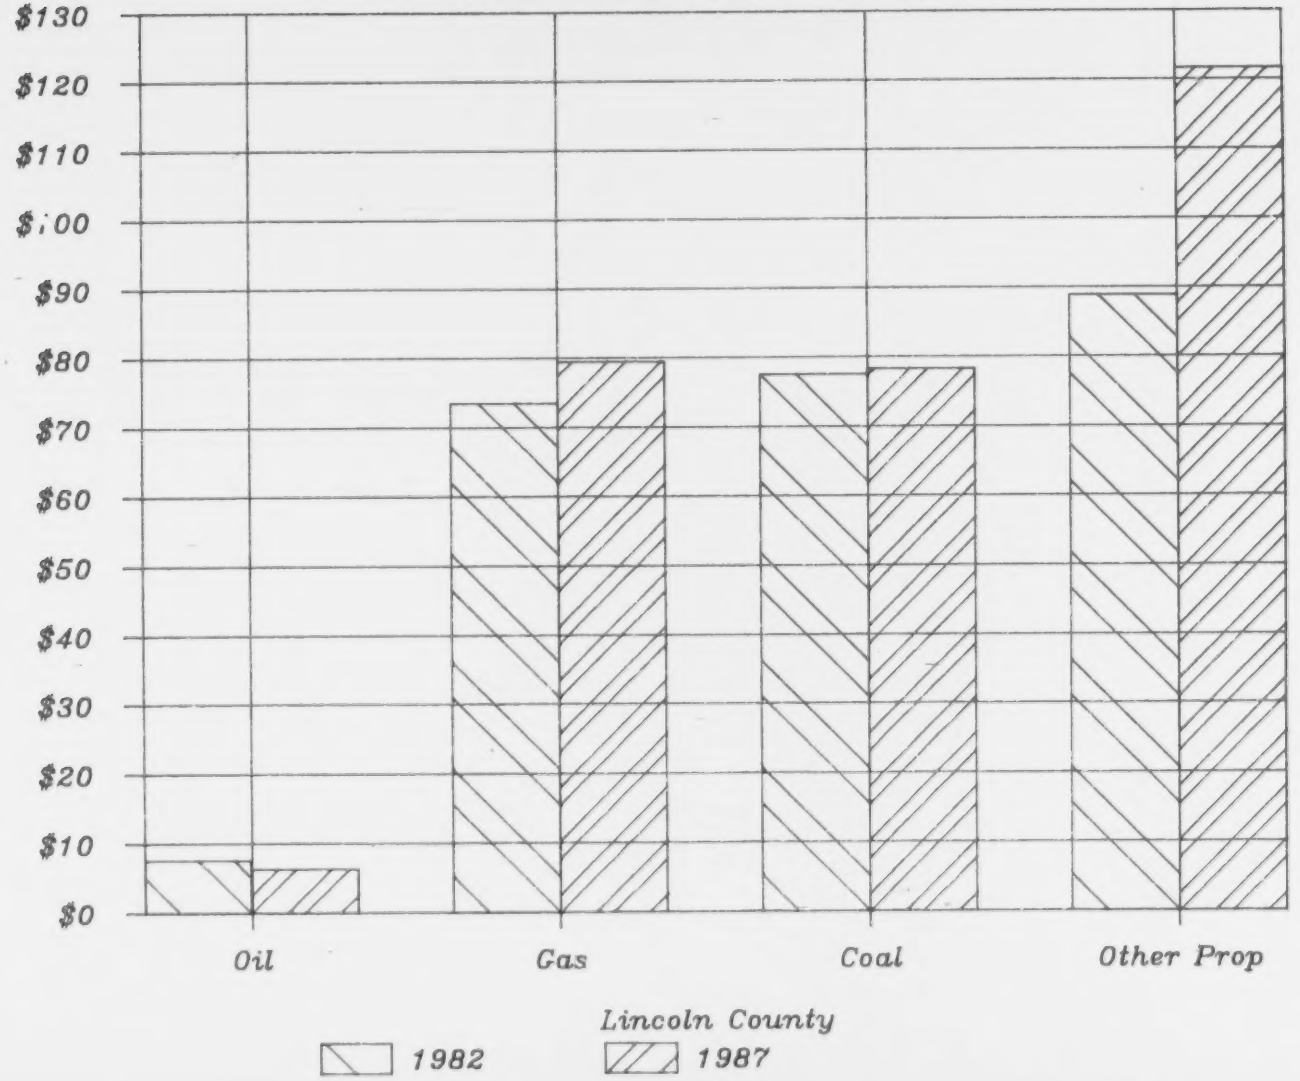
Natural gas accounted for 48% of Lincoln County's 165 million dollar mineral valuation in 1987. The county's location on the eastern edge of the Overthrust Belt accounts for its large gas production.

Lincoln County has been a coal producer for 110 years. In 1986, 4,000,000 tons were mined, a small decrease over 1985. Additional production from the FMC Skull Point Mine and possibly a Rocky Mountain Energy operation should raise this total in future years.

County oil production rose very slightly in 1986. The Exxon LaBarge Project has begun production, and will spark a rise in Lincoln County gas output.

1982 vs. 1987 Total Valuation

Breakdown by Mineral Production



NATRONA COUNTY

Oil production in Natrona County fell by over 4,000,000 barrels in 1986. A drop in unit valuation of $2.52 resulted in a loss of over 87 million dollars in valuation.

Bentonite production fell by 17,000 tons. Considering the wide fluctuations in the bentonite industry, no trends are discernable.

Other county mineral products are sodium sulfate and construction materials.

NIOBRARA COUNTY

Niobrara County's most important mineral commodity is crude oil. In 1986 crude oil accounted for 95% of the county's mineral valuation. Production rose slightly from 956,203 to 1,032,565 barrels, but a unit value decline of $10.99 was reflected in a valuation drop of over 9 million dollars.

Natural gas production rose by over 234,000 MCF, but such a small quantity cannot reliably indicate longer range trends.

PARK COUNTY

Park County was in second place behind Campbell County in 1986 with an output of 19,233,945 barrels of oil. This was an decrease of 511,000 barrels compared to 1985. Production will continue to decline as old giant fields like Oregon Basin continue to be depleted, regardless of market conditions. Oil production accounted for 95% of the county's mineral valuation and 69% of total valuation. Unit valuation fell by $11.75 per barrel.

Gas production declined slightly by 113,000 MCF.

Gypsum production was 649,000 tons in 1986, up from 172,000 tons in 1985.

PLATTE COUNTY

The county's mineral valuation, $3,519,434, comes from Guernsey Stone's dolomite quarry, Basin Engineering's marble quarry and various sand and gravel operations.

SHERIDAN COUNTY

Coal production in Sheridan County fell by over 1,000,000 tons in 1986. This resulted in a drop of 28.5 million dollars in mineral valuation. Unit valuation decreased by $2.56 per ton.

The county's coal production came from Peter Kiewit and Sons' Big Horn Mine. The Big Horn Mine will close when its contract with Commonwealth Edison expires at the end of 1988. Ninty-three percent of the mineral valuation of the county comes from this mine's production.

Sheridan County's oil production decreased by 45,243 barrels in 1986.

Construction materials, including scoria, accounted for 39,636 dollars of valuation.

SUBLETTE COUNTY

Natural gas was Sublette County's most important mineral product in 1986, with over 38 million MCF produced with a valuation of over 63 million dollars. However, both of those figures were significant losses over 1985.

As the Riley Ridge Project comes on line Sublette County's gas production will show dramatic increases.

Oil production declined in 1986 with a loss of 96 thousand barrels. Liquids stripped at the new processing plants, plus the possibility of new Overthrust discoveries, should slow this downward trend.

SWEETWATER COUNTY

Sweetwater County has significant production of oil, gas, coal, and trona and these plus sand and gravel combine for a total valuation on production of over 633 million dollars, second largest in the State.

Coal is the most valuable product, accounting for 42% of the mineral valuation and 27% of the total valuation. Production in 1986 was down 345,000 tons.

Natural gas is the second most valuable mineral commodity in the county, accounting for 24% of the mineral valuation and 15% of the total valuation.

Sweetwater County is the fourth largest oil producer in the State. Production of 7,721,000 barrels was responsible for 17% of the county mineral valuation in 1986.

Trona is produced only in Sweetwater County, and is fourth behind coal, gas, and oil in valuation at $105,506,325 dollars. Production was up by over 1.1 million tons in 1986, raising the valuation.

TETON COUNTY

Teton County is the only county in Wyoming which had no oil or gas production in 1986. A number of exploration leases and permits have been let in the county, and several wells have been drilled in the past but whether any production will result from this activity remains to be seen.

The only minerals produced in Teton County in 1986 were 55,941 dollars worth of sand and gravel.

UINTA COUNTY

Uinta County has been the main benefactor of Overthrust Belt oil and gas activity. In 1970 the county produced 31,000 barrels of crude oil while in 1986 the total was 10,854,215 barrels, third in the State behind Campbell and Park Counties. The increase in natural gas production has been as dramatic, from 3.4 million MCF to 83.8 million MCF, the largest total in the State. Uinta County valuation on oil and gas production was 74% of the total county valuation in 1986. Collapsing oil prices cost the County $175,000,000 in valuation in 1986.

Construction materials valuation was 370,000 dollars in 1986, reflecting the last phases of energy construction in the county.

WESTON COUNTY

Oil production in the county dropped by 282,000 barrels in 1986, continuing a trend first appearing in the 1960's. Considering the age of Weston County's oil fields, no reversal of this downward slope is likely.

Natural gas production rose by over 200,000 MCF, but unit valuation fell by .87 cents.

Bentonite production in the county fell by about 4,500 tons.
